Abstract

Tropospheric Ozone (O₃) is one of the most important pollutants in the atmosphere, causing some damage to human health, climate, vegetation and materials. This pollutant presents different behaviours in urban and rural environments. High levels of nitrogen oxides (precursor of O₃) in urban areas have an important role in photochemical production of O₃ in the atmosphere. However, O₃ concentrations tend to be higher in rural areas. For better understanding this phenomenon, the O₃ data at 52 rural sites in Italy were analysed in this study. It aimed the assessment of the trend and distribution of O₃ concentrations; the evaluation of the exceedances of the standard values for human health protection; the analysis of the daily maximum values of O₃ concentrations at all monitoring sites; the analysis of the annual average profiles of O₃ concentrations; the application of cluster analysis to group the monitoring sites according to the respective O₃ behaviour. The ongoing environmental monitoring data obtained from 52 monitoring stations during the period 2008-2012 were used in this study and the O₃ data analysis was performed for each year of the mentioned period. It concluded from the results that the O₃ concentration at the different rural sites and the daily the maximum concentrations had different behaviour over the study period. Cluster analysis divided the monitoring sites in six groups according to their O₃ concentration behaviour. The observed differences for the different groups related to the geographical location and altitude of the monitoring sites. All these results will provide a physical basis for accurately predicting ozone concentration in extensive future research.

Keywords: O₃ concentration; pollutant; cluster analysis.

1. Introduction

Over the past few years, air pollution has become a serious problem on a global scale due to changes in human activities which have a significant importance on the alteration of the atmosphere characteristics and consequently in ecosystems and human health. In this way, there has been seen an increasing concern of many institutions, governments, scientific community and the world population in general about the effects of photochemical pollution and particles [7].

Tropospheric ozone, characterized as a photochemical pollutant and a strong oxidant is generator of various impacts on human health, vegetation and materials. Even though the contribution of hydrocarbons released from plants and soil and the ozone migration from the stratosphere is low, ground-level ozone as a byproduct of human activities contributes significantly to both air quality and environment degradation [1].

Italy which is a country in Southern Europe, part of the Mediterranean Basin, is generally affected in the spring and summer by episodes of photochemical pollution. Italy is an important economic center in the world which has serious air pollution problems derived from emissions of various pollutants from large urban centers and industrial clusters. The typical climate of this region and its geographic features characterize the appropriate environment for the occurrence of photochemical pollution episodes [8].

In this regard, the European Union has made efforts in order to issue a number of laws with the aim to protect human health, inform and alert the population. The European Union also aims that the authorities use the database as a decision-making support on strategic plans and programs to reduce emissions and improve air quality [2]. The present work is a contribution to the understanding of ozone behavior in Italy.

2. Material and Methods

In this study is presented the O₃ behavior at 52 rural sites in Italy, during the fiscal years of 2008 and 2012, aiming: I) the assessment of the trend and distribution of O₃ concentrations; II) the evaluation of the exceedances of the standard values for human health protection; III) the analysis of the annual average profiles of O₃ concentrations; IV) the analysis of the daily maximum values for O₃ concentrations at all monitoring sites; V) the application of cluster analysis (CA) to group the monitoring sites according to the respective O₃ behaviors. Regarding the last objectives (IV and V) we are going to discuss in a future paper, because the data are still in processing.

2.1. The selection of the air quality stations

At an early stage, based on the central objective of this study, were selected fifty-two rural monitoring stations but after the application and verification of the compliance with a legal requirement which set the annual collection efficiency higher or equal to 60% for each monitoring station, the sample of fifty-two monitoring stations was reduced to thirty. The monitoring data were obtained from the Superior Institute for Protection and Environmental Research's website [3].

2.2 The characterization of the monitoring sites

After the selection of the monitoring sites, the next step was to collect information concerning their location, the altitude and the main pollution source (traffic, industrial or background). Most of the data were obtained from information available in the respective websites of the Regional Agencies for Environmental Protection in Italy, while the remainder from environmental reports published by these agencies. In table 1. are presented the geographical coordinates, altitude and the date of activation for each monitoring site:

Table 1- Geographical coordinates and altitude of the monitoring sites and their starting date (SD) of O₃

The main pollution source of the monitoring sites is background. CCS is the only monitoring site with industrial source pollution. Figure 1 shows a map with the spatial distribution of the monitoring sites in Italy.

Figure 1. Map with the spatial distribution of the monitoring sites in Italy

2.3. Data processing

Initially, we proceeded to the organization of data in Excel spreadsheets. Afterwards was carried out a statistical approach, including the calculation of averages, maximums, minimums, medians, daily profiles, annual profiles and exceedances to the EU limit values. This process was quite time consuming and required the development and application of macros in Excel, in order to reduce the probability of committing calculation errors and to accelerate the execution time of all the implemented processing.

3. Results and Discussion

The table 2 shows the monitoring site efficiencies and the number of exceedances of surface O₃ concentrations to EU standards for protection of the human health during the studied period. Missing data for the following monitoring station (i) MAG and (ii) CCF were interpolated from the annual average value of the monitoring station.

The majority of monitoring stations have not exceeded the alert threshold ($240 \mu\text{g m}^{-3}$ for hourly average). Therefore, it is possible to identify the monitoring sites which exceeded the standard limit, specifically (i) VVA, (ii) LBG, (iii) LLM, (iv) LSC, (v) LRC, (vi) LFF, (vii) LRL and (viii) SSS. The LLM site was the only monitoring site that exceeded the standard limit in the first three years of the study period. Most of the monitoring sites exceeded the information threshold ($180 \mu\text{g m}^{-3}$ for hourly average), except (i) VAE, (ii) TAA, (iii) CCS, (iv) TGG, (v) PLL, (vi) MAG, (vii) CCF, (viii) MAM. According to the results, the monitoring sites VAL and LRC only exceeded once the standard limit during all study period. It is seen that the sites VVA and LLM which are located at high altitudes, 1363 and 1194 respectively, showed the highest numbers of exceedances. Regarding the target value for the protection of human health ($120 \mu\text{g m}^{-3}$ for a maximum of daily 8 h averages), in all the monitoring sites were found higher O₃ concentrations than the defined limit. The EU target limit for the human health protection was respected at VAL, LRC, CCS, SSS and CCF. The result reveals that previous mentioned sites had lower concentrations when comparing to the target limit which is 25 days a year, averaged over 3 years.

Table 2. Monitoring sites efficiency in percentage (ME) and number of exceedances of surface O₃ concentrations to EU standard values for protection of human health during the study period: (i) information threshold (IT); (ii) alert threshold (AT); and (iii) the target value (TV)

The figure 2 shows the annual average O₃ concentrations at the studied rural sites, the following monitoring sites presented the highest concentrations in 2012, (i) VVA, (ii) CCS, (iii) MAG, (iv) MCG, (v) VAL, (vi) LFF, (vii) MIV and (viii) CCF.

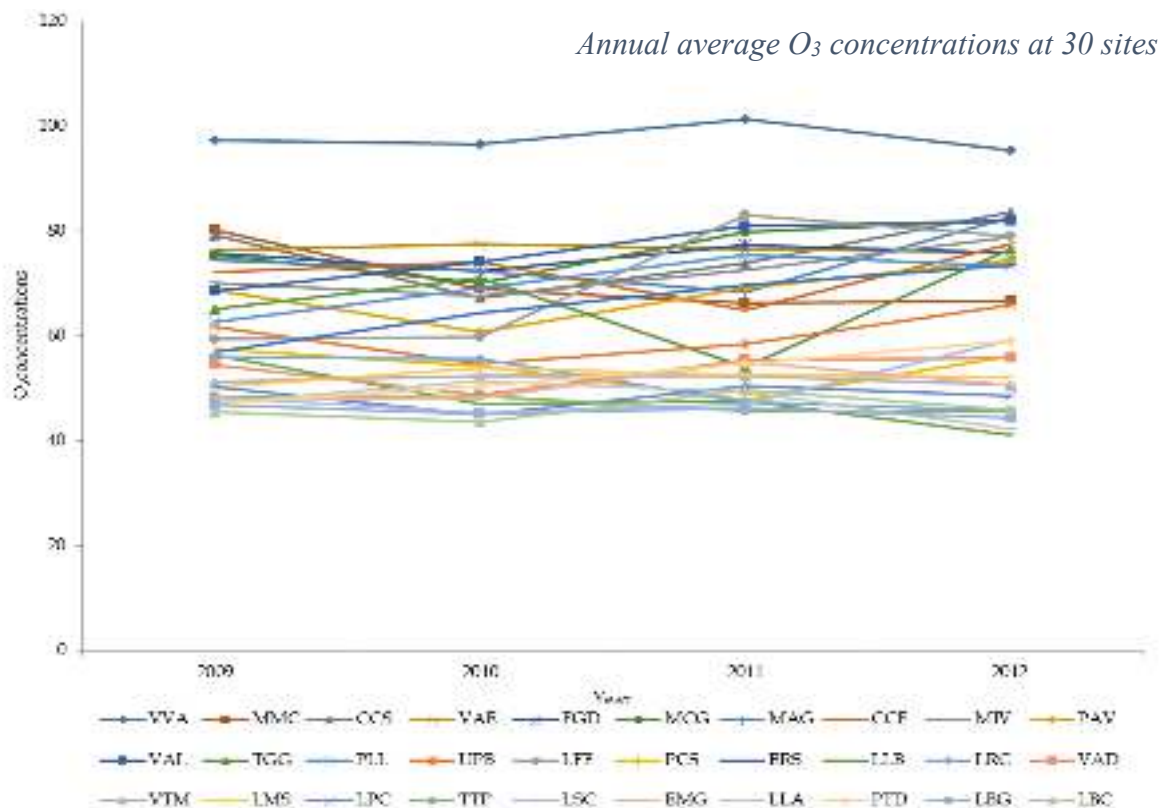

Figure 2. Annual average O₃ concentrations ($\mu\text{g m}^{-3}$) at the different rural sites during the studied period

It also shows that the ozone behavior varies depending on the monitoring stations. For instance, the MMC site showed a decreasing trend during the study period, having achieved a reduction of $-11 \mu\text{g m}^{-3}$ between 2009 and 2010 as well as a reduction of $-3 \mu\text{g m}^{-3}$ between 2010 and 2011, remaining constant for the following year.

4. Conclusions

- During the study period, O₃ concentrations presented the highest values in 2011 and 2012, periods when high concentrations were recorded.
- Concerning the exceedances of the thresholds defined in the European Directives, to protect human health, we can see that the alert threshold has been exceeded from (i) VVA, (ii) LBG, (iii) LLM, (iv) LSC, (v) LRC, (vi) LFF, (vii) LRL and (viii) SSS sites, among which LLM site was the only monitoring site that exceeded the standard limit in the first three years of the study period.
- The information threshold was exceeded from most of the monitoring sites. VVA and LLM sites, which are located at high altitudes, 1363 and 1194 respectively, showed the highest numbers of exceedances, while Regarding the target value for the protection of human health, in all the monitoring sites were found higher O₃ concentrations than the de-fined limit except VAL, LRC, CCS, SSS and CCF.
- The study carried out in this rural areas may contribute to improve the knowledge of ozone dynamics in Italy, which is part of the Mediterranean basin.
- All these results will provide a physical basis for accurately predicting ozone concentration in extensive future research.
